

SITE NARRATIVE

SITE NAME: Palos Verdes Shelf Sediment Contamination

EPA ID NO.: CAD008242711

Sediments on the seafloor southwest of the Palos Verdes Peninsula in Southern California contain the chlorinated pesticide dichlorodiphenyltrichloroethane (DDT) and its metabolites and polychlorinated biphenyls (PCBs) from years of effluent discharge from the White's Point outfalls of the Los Angeles County Sanitation Districts. Releases of hazardous substances peaked in the early 1970s, after which source controls and treatment technologies reduced the rates of discharge of DDT, PCBs, and settleable solids. Less-contaminated effluent and natural sedimentation has buried some of the contamination. Existing surface contamination and physical, chemical, and biological processes that bring contaminants to the sediment surface result in the release of hazardous substances to the environment where uptake by benthic organisms and fish carries the contaminants higher up the food chain.

The Palos Verdes Shelf extends seaward along a 12-kilometer stretch of coastline that ranges in width from 4 kilometers near Point Fermin on the east to 1.5 kilometer near Point Vincente on the west. The volume of effluent-affected sediments on the shelf is approximately 8.2 million cubic meters. It covers an area of approximately 13.5 square miles. The contaminated sediments are covered by 30 to 500 meters of water.

The Palos Verdes Shelf supports several commercial and sport fisheries. White croaker (*Genyonemus lineatus*), bottom-feeding fish that reside on the Palos Verdes Shelf, contain levels of DDT and PCBs that have resulted in the California Environmental Protection Agency's Office of Health Hazard Assessment issuing health advisories against the consumption of white croaker caught from White's Points or anywhere along the Palos Verdes Shelf. The commercial white croaker fishery is also closed in this area.

Humpback whales (*Megaptera novaenaglie*) have been observed migrating through the San Pedro Channel. Brown pelican (*Pelecanus Occidentalis*), bald eagle (*Haliaeetus leucocephalus*), and peregrine falcon (*Falco peregrinus*), federally listed endangered species, inhabit the Santa Barbara Channel Islands and forage throughout the Southern California Bight.

All species have low breeding success in this area which has been attributed to high concentrations of DDT in the birds and their eggs. Biomagnification of DDT via gulls, other sea birds, and marine mammals is the main cause of high DDT residues still observed in bald eagles and peregrine falcons. While studies of the problem do not contend that all of the contamination observed in the birds that live in the Southern California Bight area comes from biomagnification of the contamination in the effluent-affected sediments on the Palos Verdes Shelf, they do feel that this is an important source.

There are no freshwater aquifers beneath the contaminated sediments. The water column above the sediments restricts the potential for direct contact or the release of contaminants to the air.

HRS DOCUMENTATION RECORD—REVIEW COVER SHEET

Name of Site: **PALOS VERDES SHELF SEDIMENT CONTAMINATION**

Contact Person: **Carolyn Douglas, EPA Region IX** **(415) 744-2343**

Site Investigation: **Karen Johnson, Ecology and Environment, Inc.** **(415) 981-2811**

Documentation Record: **Karen Johnson, Ecology and Environment, Inc.** **(415) 981-2811**

Pathways, Components, or Threats Not Evaluated:

The groundwater pathway was not quantified because the effluent-affected sediments sit offshore and there are no useable aquifers beneath the sediments. The soil exposure and air pathways were not quantified because the sediments are located beneath 30 to 500 meters of ocean water.

CONVERSION FACTORS

Many of the documents cited in this Documentation Record use the metric system for presenting all measurements, including distance, area, and volume. The Documentation Record reports these data in their original units, except where comparison with units in the Hazard Ranking System (HRS) is required; measurements are only converted from metric where HRS factors are assigned.

1 kilometer	(km)	= 0.62 mile
1 centimeter	(cm)	= 0.39 inch
1 square meter	(m ²)	= 10.76 square feet
1 square kilometer	(sq km)	= 247 acres
1 cubic meter	(m ³)	= 1.307 cubic yards
1 metric ton	(Mg)	= 2,204.6 pounds
1 liter	(L)	= 0.264 gallon

SOURCE DESCRIPTION

2.2 Source Characterization

Source Description: Source 1 — Effluent-Affected Sediments

Sediments on the seafloor off the coast of the Palos Verdes Peninsula in Southern California have been impacted by the effluent discharged from the White's Point outfalls of the Sanitation Districts of Los Angeles County (LACSD) (ref. 3, p. ES-7). In 1937, LACSD began to discharge treated municipal and industrial wastewater through the White's Point ocean outfall on the Palos Verdes Shelf. Two new pipe diffuser systems were added in 1956 and 1966 to accommodate increasing discharges from the LACSD Joint Water Pollution Control Plant (JWPCP). The discharges of wastewater and suspended solids peaked in 1971 at about 360 million gallons per day and 167,000 metric tons per year, respectively (ref. 5, p. 1). The JWPCP effluent contained several pollutants—in particular, dichlorodiphenyltrichloroethane (DDT) and its metabolites and polychlorinated biphenyls (PCBs) (ref. 5, pp. 1 and 2; ref. 6, p. 1.9). After source control and treatment technologies improved in the early 1970s, the discharge rate of DDT, PCBs, and suspended solids through the outfalls decreased. Monitoring by LACSD showed that the amount of DDT and PCBs in surface sediments on the Palos Verdes Shelf began to decrease as the contaminated sediments were gradually covered with less contaminated effluent and natural sediment (ref. 5, p. 2). However, the concentrations of DDT (and dichlorodiphenyldichloroethylene [DDE], one of its metabolites) in surface sediments have remained higher than the emission rates from the JWPCP indicate they should be (ref. 5, pp. 2-3). A study on the natural recovery of the contaminated sediments suggests that older, buried DDE or DDT gets mixed into the upper surface through physical, chemical, or biological processes and is contributing to the current contaminant levels in the surficial sediment layer on the shelf (ref. 5, pp. 2-4). This historical "reservoir" of effluent-affected sediments is being evaluated as Source 1.

Source Location

The effluent-affected sediments of Source 1 exist on the Palos Verdes Shelf and extend down the continental slope to a water depth of at least 500 meters (m) (ref. 3, p. 120). The shelf extends seaward along a 12-kilometer (km) stretch of coastline on the southwest side of the Palos Verdes Peninsula, Los Angeles County, California, and ranges in width from 4 km near Point Fermin on the east to 1.5 km near Point Vicente on the west (see Figure 1) (ref. 3, p. ES-2; ref. 4). The continental slope lies south of the shelf and has a mean slope of 13° leading to the 800-m-deep San Pedro Basin (ref. 3, p. ES-2). East of Point Fermin, the peninsula runs northward into Los Angeles Harbor. The Palos Verdes Peninsula marks the southern edge of Santa Monica Bay (ref. 4).

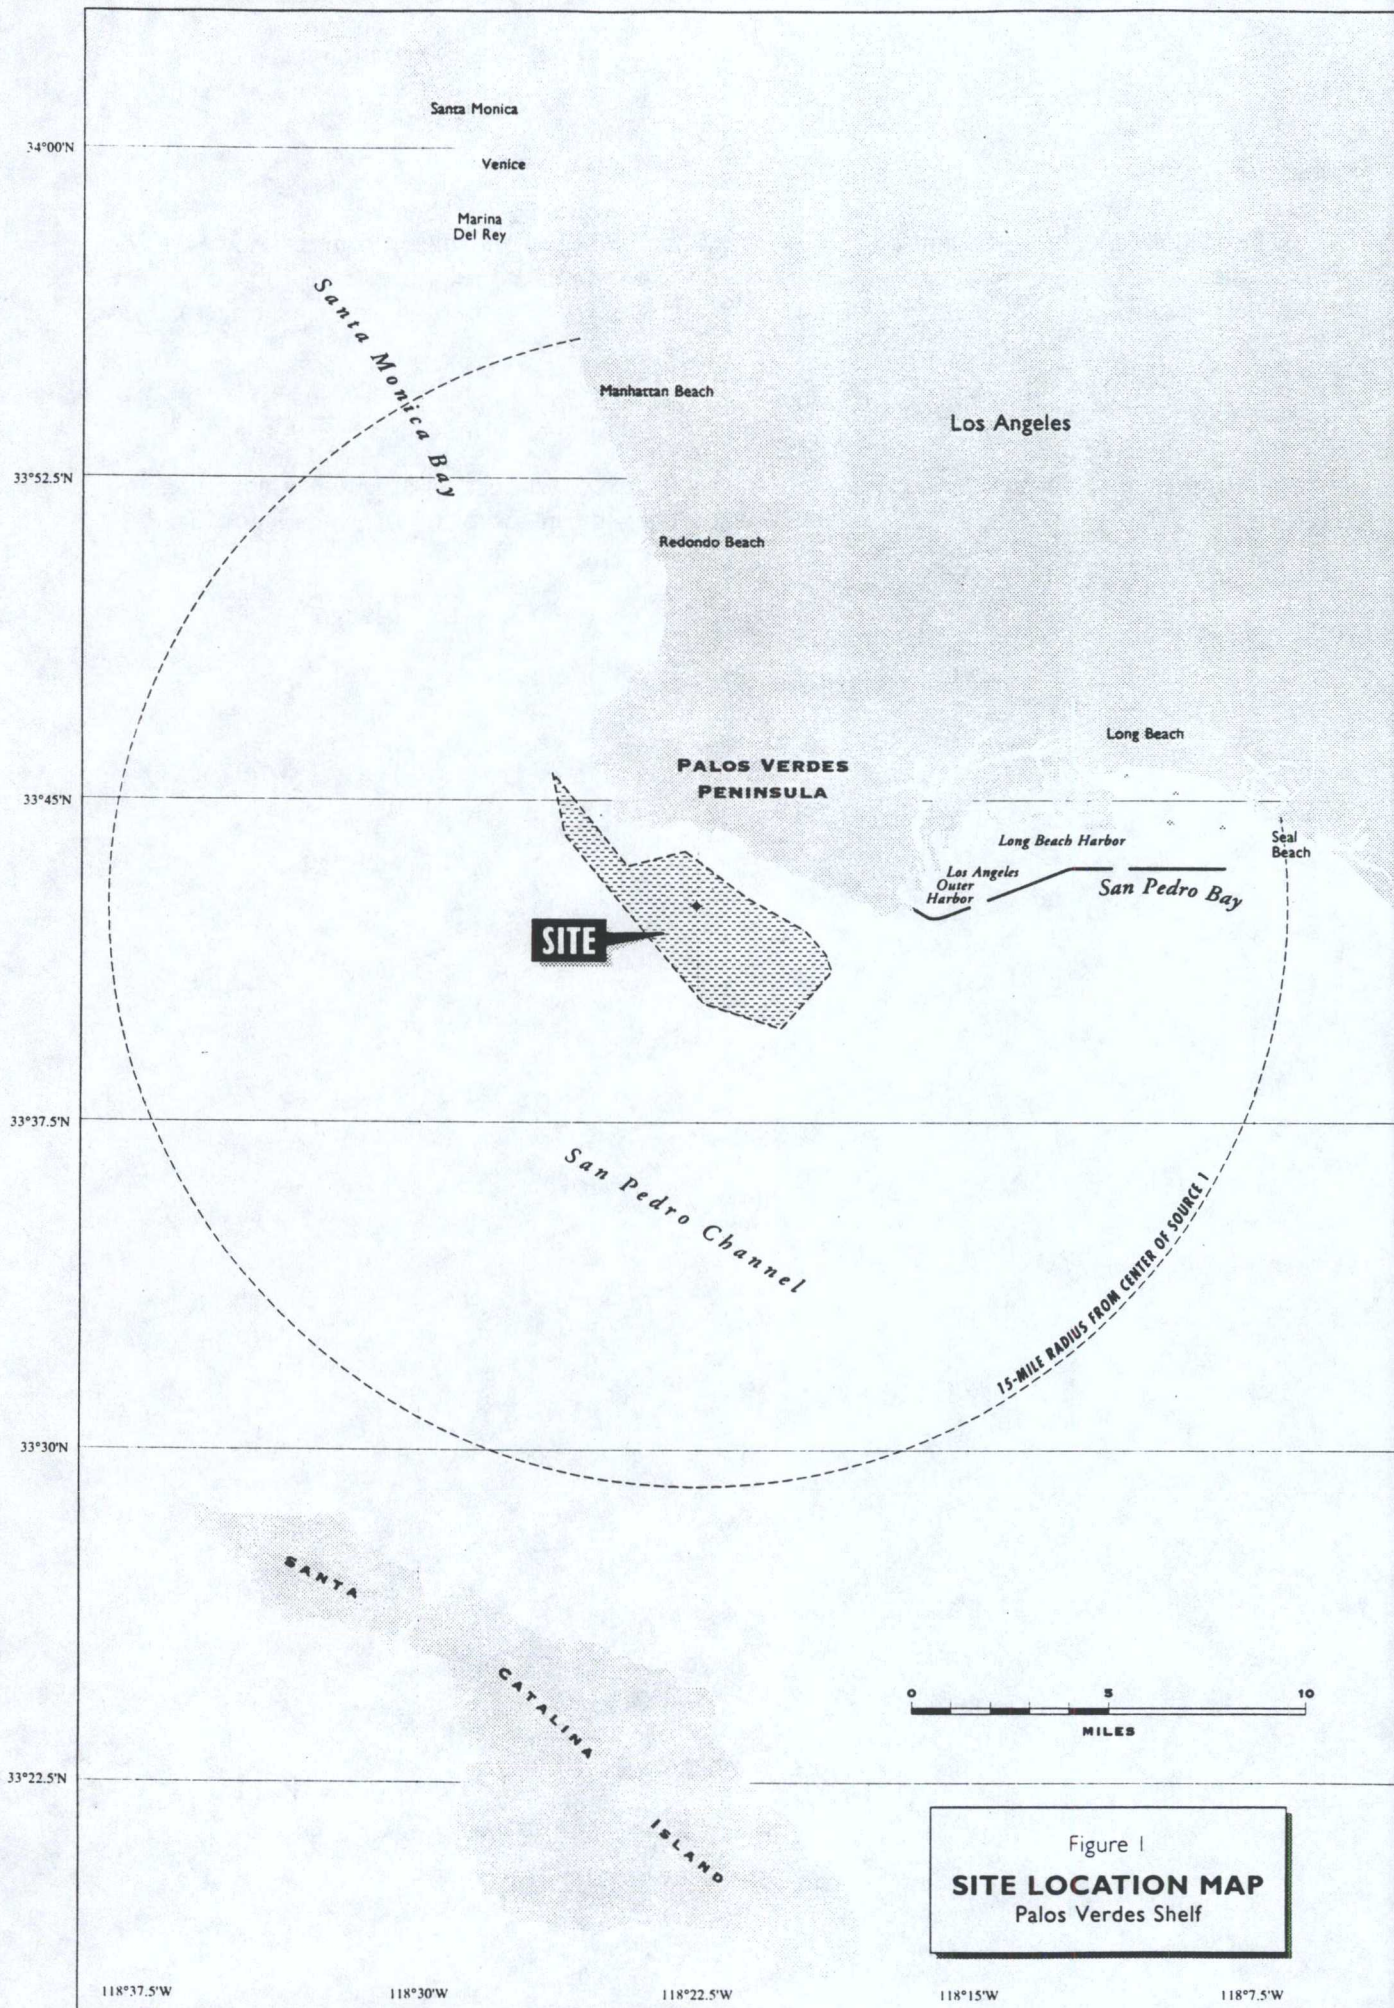

Source Containment

Gas Release to Air

The contaminated sediments are covered by 30 to 500 meters of water (ref. 3, p. 120). Gases would need to volatilize through the water column to be available for a release to air. The air pathway is not being evaluated, so no gas release to air containment factor was assigned.

Particulate Release to Air

The contaminated sediments are covered by 30 to 500 meters of water (ref. 3, p. 120). The air pathway is not being evaluated, so no particulate release to air containment factor was assigned.

Release to Groundwater

The effluent-affected sediments rest on the ocean floor with no containment features; however, the site is in the ocean with no freshwater aquifer beneath the contaminated sediments (ref. 7, p. 38). The groundwater pathway is not being evaluated, so no groundwater pathway containment factor was assigned.

Release to Surface Water

Contaminated sediments exist on the ocean floor with no cover, liner, or other containment feature (ref. 3, pp. 105, 108, 111, and 117). A surface water containment factor of 10 was assigned (ref. 1, Table 4-2).

2.4.1. Hazardous Substances

As part of a Natural Resource Damage Assessment (NRDA) completed by the U.S. National Oceanic and Atmospheric Administration (NOAA), the U.S. Geological Survey (USGS) conducted a multidisciplinary study to characterize the geometry of the effluent-affected sediments and the corresponding concentrations of DDT and PCBs on the Palos Verdes Shelf (ref. 3, p. ES-1).

The USGS sediment study included, among other things, collection and analysis of 37 sediment core samples for DDT and PCBs in July 1992 (ref. 3, p. 3). These samples were evaluated to determine the presence of hazardous substances and the hazardous waste quantity in Source 1. Of these 37 sediment core samples, 28 document the presence of hazardous substances in Source 1, specifically, PCBs and DDT (both 2,4- and 4,4-DDT) and its metabolites (2,4- and 4,4-DDE; 2,4- and 4,4-DDD; 4,4-DDD olefin [DDMU]). Table 1a describes the samples selected to represent background conditions; Table 1b presents the analytical results for total PCBs and the seven DDT isomers/metabolites for these samples. Table 2a describes the samples documenting the presence of hazardous substances in Source 1; Table 2b presents the analytical results for total PCBs and the seven DDT isomers/metabolites for these samples.

Table 2b lists the analytical results for surface increments (0-2 or -4 cm) and the increment at depth that contained the highest concentration of at least one of the hazardous substances for that core sample. For some core samples, more than two non-surface increment samples are reported in the table because different increments contained the highest concentration of different compounds. At least one hazardous substance in each sample increment included on the table meets the requirements of an observed release described in ref. 1, Table 2-3 (see also discussion of observed release criteria in Section 4.1.1.2.)

DDT and PCBs

The pesticide DDT was discovered in 1874 and saw widespread use as a delousing and mosquito control agent during World War II (ref. 13, p. 16-1). DDT degrades or metabolizes to DDE and dichlorodiphenyldichloroethane (DDD). Total DDT consists of the sum of six individual compounds: p,p'-DDE; o,p'-DDE; p,p'-DDD; o,p'-DDD; p,p'-DDT; and o,p'-DDT. p,p'-DDE is the dominant compound of DDT in the environment and the concentration of total DDT is normally little different from the concentration of p,p'-DDE alone (ref. 3, p. ES-1; ref. 13, p. 16-1; ref. 14, p. 2). [Chemistry note: the o and p in the above compound abbreviations refer to the ortho and para placement for di-substituted chlorinated compounds. These abbreviations can also be listed by number—2 for ortho or 4 for para (ref. 15, p. 126).]

There are 209 different compounds that can be formed when basic biphenyl is chlorinated. These various compounds are called congeners (ref. 14, p. 2; ref. 16, p. 2). The stability of the various congeners of PCBs varies greatly; however, in general, the more highly chlorinated compounds are the most stable. Many of these congeners can persist in the environment for many years (ref. 14, p. 2).

Sampling and Analysis Methodologies

Figure 2 shows the station numbers for all 60 core samples collected by the USGS (only 37 of the 60 were analyzed for DDT and PCBs). The following numbering system was used by the USGS for this study: Each coring station was assigned a three-digit number beginning with a 5. The numbering system proceeded roughly from west to east across the study area (ref. 3, p. 3). Some of the coring stations were sampled in both 1992 and 1993. Individual core samples collected in 1992 were given a three-digit designation beginning with a 1. Core samples taken in 1993 were assigned a 3-digit designation beginning with a 2. Standard box cores (20-cm by 30-cm surface area) were given a designator "B,"

giant box cores (50-cm by 50-cm) were given a designator "W," and gravity cores were given a designator "G." The last digit in the sample number relates to the attempt number (sometimes more than one attempt was made to get a particular core sample) at a given location. A typical sample number is 156-B1 (ref. 3, p. 5).

The sediment core samples collected by the USGS were analyzed by Arthur D. Little, Inc., (ADL) in Cambridge, Massachusetts. The chemistry performed at ADL was subject to a Quality Assurance (QA) Plan for the Southern California NRDA (ref. 9, p. 1). According to the QA Plan, no official procedures have been approved by regulatory agencies for low-level (i.e., parts per billion [ppb]) analysis of DDT compounds or PCB congeners in marine sediments or biological tissue; therefore no particular analytical method was specified (ref. 11, p. 21). The laboratory was required to provide written protocols for the analytical methods used and to participate in interlaboratory comparison exercises managed by the National Institute of Standards and Technology (NIST) for NOAA and the U.S. Environmental Protection Agency (EPA) (ref. 11, p. 17; ref. 12). Laboratory and validation qualifiers were attached to sample results to assist in data quality interpretation. These qualifiers are presented, where appropriate, in Tables 1b and 2b. Any result attached to an "R" qualifier was not added to the table. An "R" means the results are unreliable and should not be used (ref. 9, p. v).

Total PCBs were calculated by summing the concentrations of PCB congeners 8, 18, 28, 44, 52, 66, 101, 105, 118, 128, 138, 153, 170, 180, 187, 195, 206, and 209, and then multiplying by two (ref. 8, p. I-35; ref. 9, p. vi). If a congener result was reported as non-detect, then one-half of the method detection limit was used in the summation for total PCBs. A laboratory qualifier of NR was used if more than one-half of the total was contributed by non-detect results or results less than the method detection limit (ref. 9, p. vi).

Table 1a					
July 1992 USGS Sediment Core Samples Representing Background Conditions					
Station Number	Core Number	Longitude (decimal degrees W)	Latitude (decimal degrees N)	Water Depth (m)	Length of Core (cm) ¹

■ Analyte concentration (or method detection limit if followed by "U") used for comparison to document the presence of hazardous substances.

NA = Not available.

Data Qualifiers (ref. 9, p. vi):

U Analyte was not detected. Reported value is the method detection limit.

J Confirmed as present, but at a concentration less than the method detection limit.

NCA Analyte could not be confirmed on the second GC column because of analytical interferences.

SC Surrogate was diluted out of range. Result was corrected for the surrogate recovery in the undiluted analysis of the same sample extract. Data validators determined that the data met accuracy and precision requirements.

/J The reported concentration may not be accurate, as judged by associated calibration, reference material, and/or matrix spike results, or precise, as judged by associated replicate results. Overall goals for results at least five times above the method detection limit were approximately $\pm 50\%$ for precision and $\pm 35\%$ for accuracy.

Analyte concentration meets the definition of an observed release (same criteria used to document the presence of hazardous substances) (Ref 1, Table 2-3). If data is qualified with a /J, an adjustment value was applied as described in Ref. 23. For 4,4-DDD and 4,4-DDE, the sample result was multiplied by 10 before applying the criteria in Ref. 1, Table 2-3. For 4,4-DDT, an adjustment factor of 12.82 was applied (ref. 23, pp. 7, 8, 16).

NA = Not available.

Data Qualifiers (ref. 9, p. vi):

- U Analyte was not detected. Reported value is the method detection limit.
- J Confirmed as present, but at a concentration less than the method detection limit.
- NCA Analyte could not be confirmed on the second GC column because of analytical interferences.
- SC Surrogate was diluted out of range. Result was corrected for the surrogate recovery in the undiluted analysis of the same sample extract. Data validators determined that the data met accuracy and precision requirements.
- /J The reported concentration may not be accurate, as judged by associated calibration, reference material, and/or matrix spike results, or precise, as judged by associated replicate results. Overall goals for results at least five times above the method detection limit were approximately $\pm 50\%$ for precision and $\pm 35\%$ for accuracy.

2.4.2 Hazardous Waste Quantity

Tier A: Hazardous Constituent Quantity

There is insufficient data to document hazardous constituent quantity for Source 1; therefore, a 0 is assigned for this source (ref. 1, Section 2.4.2.1.1).

Hazardous Constituent Quantity Value: 0

Tier B: Hazardous Wastestream Quantity

There is insufficient data to document hazardous wastestream quantity for Source 1; therefore, a 0 is assigned for this source (ref. 1, Section 2.4.2.1.2).

Hazardous Wastestream Quantity Value: 0

Tier C: Source Volume

For this evaluation, the volume of PCB- and DDT-contaminated sediments was calculated using the sampling data from the 1992 USGS coring activity (ref. 10, p. 1). All core samples in which at least one sample increment from the core contained PCBs or one of the DDT isomers/metabolites at a concentration at least three times greater than the concentration of the same hazardous substance at the same increment in the background cores were used to calculate the volume of Source 1; 28 cores met this criteria and were used in the volume calculations.

All 28 sample locations were mapped using Golden Software's Surfer™ for Windows, Version 5.03. Table 2a contains the station number, latitude and longitude, and the thickness used to calculate the volume based on the lower edge of the deepest sampling increment reported in Table 2b. Because there is evidence that the surface of the sediments in the area have been contaminated at least in part by the upward migration of hazardous substances buried historically, the surface of Source 1 was considered the surface of the ocean sediments (ref. 5, p. 3 and 4). The lower edge of Source 1 was evaluated as the lower edge of the sample increment with the highest concentration of hazardous substances. For example, on Table 2b the highest concentration of either PCBs or the DDT isomers/metabolites at Core Station 552 was found in the 12- to 16-cm sample increment; therefore, the thickness of Source 1 at Core Station 552 is 16 cm.

Surfer™ calculated the volume within the boundary of the points and thicknesses four ways: by Trapezoidal Rule, Simpson's Rule, and Simpson's 3/8 Rule, and by using cut and fill volumes. Although the methods produced different results out to five significant digits, all four methods agreed that the volume of the sediment layer was approximately 7.0 million cubic meters (m³) (ref. 10, p. 4).

The above sediment volume calculation is supported by volume estimates conducted for the USGS sediment study. Within the USGS study, the volume of the effluent-affected sediment layer was estimated four ways (ref. 3, pp. 18-28). The values obtained are presented in Table 3 (ref. 3, p. 73). The chirp profiling method produced a result much smaller than the other three methods because it was only able to survey part of the sediment layer (ref. 3, p. 27). The average volume from the other three calculations is $(8.95 + 9.83 + 7.8)/3 = 8.9$ million m³, which is similar to the value calculated with the Surfer™ software (ref. 3, p. 73; ref. 10, p. 4). The volume calculated by Surfer™ is smaller than the other volume because only the distance between the surface and the depth of highest hazardous substance concentrations was used as the thickness of Source 1. In addition, a "blanking" file was used to cut off the edges of the shape to be calculated rather than extrapolating the edges out to a 0-m thickness (ref. 10, pp. 1 and 3).

To assign a waste quantity factor value for Source 1, the effluent-affected sediments, 7.0 million m³ was converted to 9.2 million cubic yards (yd³) by multiplying by 1.307. For a source type of "other", the volume of Source 1 was converted to hazardous waste quantity by dividing by 2.5; therefore, the volume of 9.2 million yd³ converts to a hazardous waste quantity value of 3.68×10^6 (ref. 1, Table 2-5).

Dimension of Source (yd³): 9.2 million

Volume Assigned Value: 3.68×10^6

DDE = dichlorodiphenyldichloroethylene

LACSD = Los Angeles County Sanitation Districts

m = meters

m³ = cubic meters

USGS = U.S. Geological Survey

Tier D: Source Area

Because the volume of Source 1 was adequately determined, the area was not calculated (ref. 1, Section 2.4.2.1.3).

Area Assigned Value: 0

Source Hazardous Waste Quantity

The Source Hazardous Waste Quantity for Source 1 is derived from Tier C: Volume (ref. 1, Section 2.4.2.1.5).

Source Hazardous Waste Quantity: 3.68×10^6

GROUNDWATER MIGRATION PATHWAY

3.0.1 General Considerations

There are no fresh water-bearing sediments in the southwestern Palos Verdes Hills or in the offshore area of the Palos Verdes Shelf; therefore, there is no pathway for hazardous substances to migrate from the effluent-affected sediments to the groundwater aquifers of the Los Angeles Coastal Plain (ref. 7, p. 38).

Groundwater Pathway Score: 0

SURFACE WATER MIGRATION PATHWAY

4.1 OVERLAND/FLOOD MIGRATION COMPONENT PATHWAY DESCRIPTION

4.1.1 General Consideration

4.1.1.1 Definition of Hazardous Substance Migration Path for Overland/Flood Component

The source of hazardous substances for release to the surface water pathway is a body of effluent-affected sediments resting on the ocean floor at water depths of between 30 and 500 m (ref. 3, pp. ES-7 and 120). These sediments contain PCBs and isomers and metabolites of DDT in concentrations significantly higher than background levels (ref. 3, pp. 53-62; ref. 9, pp. 1-120). The interface between hazardous substances in the surface layer of the effluent-affected sediments and the ocean provides the mechanism for release of hazardous substances to the ocean; therefore, the surface of Source 1 is the probable point of entry of hazardous substances to surface water.

Shelf currents are generally slow, averaging 7 to 10 centimeters per second (cm/s), and trend to the northwest along bathymetric lines (ref. 6, p. 3.3). The effluent containing hazardous substances discharged through outfall diffusers at a depth of 61 m (ref. 6, p. 3.2). The effluent-affected sediment deposit is an oval mound whose long axis extends northwest along the 50 to 60 meter bathymetric line. The mound's southeastern end rises relatively steeply, and a long gentle slope tapers off to the northwest of the outfall system. The side of the mound nearest to shore ends abruptly at a water depth of about 30 meters; however, the offshore flank drapes over the shelf break and extends down the continental slope (ref. 6, p. 3.3). The shape of the effluent-affected sediment deposit shows that although the dominant current flows to the northwest there is some mixing by waves and storms.

Because there is no clearly defined flow to the water above the effluent-affected sediments, the target distance limit for the surface water migration path is an arc with a radius of 15 miles (or 24 km) extending from the center of the effluent-affected sediment deposit as shown on Figure 1 (ref. 1, Section 4.1.1.2). Using the half-way point between the latitudes for core stations 514 and 584 and the longitudes for core stations 514 and 577, listed on Table 2a and shown on Figure 2, the center of the sediment deposit was calculated as latitude 33° 42' 38" N., longitude 118° 22' 32" W. (ref. 3, pp. 50-62 and 78).

4.1.1.2 Observed Release

Direct Observation

An observed release by direct observation has not been documented for this site.

Chemical Analysis

An observed release by chemical analysis can be documented to surface water using the 1992 USGS sediment core data. Table 4a describes the samples selected to represent background conditions; Table 4b presents the analytical results for total PCBs and the seven DDT isomers/metabolites for these samples. The shaded values on Table 4b are the highest concentration (or highest method detection limit for undetected results) of the four background core samples for a particular hazardous substance at a particular sample increment and were used in applying the conditions for documenting an observed release presented in ref. 1, Table 2-3.

<p>Table 4a</p> <p>July 1992 USGS Sediment Core Samples Representing Background Conditions</p>

■ Analyte concentration (or method detection limit if followed by "U") used for comparison to document an observed release to surface water.

NA = Not available.

Data Qualifiers (ref. 9, p. vi):

U Analyte was not detected. Reported value is the method detection limit.

J Confirmed as present, but at a concentration less than the method detection limit.

NCA Analyte could not be confirmed on the second GC column because of analytical interferences.

SC Surrogate was diluted out of range. Result was corrected for the surrogate recovery in the undiluted analysis of the same sample extract. Data validators determined that the data met accuracy and precision requirements.

J The reported concentration may not be accurate, as judged by associated calibration, reference material, and/or matrix spike results, or precise, as judged by associated replicate results. Overall goals for results at least five times above the method detection limit were approximately $\pm 50\%$ for precision and $\pm 35\%$ for accuracy.

Table 5a describes the samples meeting the requirements of an observed release while Table 5b presents the analytical results for total PCBs and the seven DDT isomers/metabolites for these samples. Table 5b lists the analytical results for surface increments (0-2 or -4 cm) and the increment at depth that demonstrated an observed release of at least one of the hazardous substances for that core sample when compared to the background samples for the same increment. The shaded values on Table 5b meet the following requirements of an observed release (adapted from ref. 1, Table 2-3 for the specific circumstances in this evaluation):

- If the background concentration is not detected (or is less than the detection limit), an observed release was established when the sample measurement equaled or exceeded the background method detection limit.
- If the background concentration equaled or exceeded the method detection limit (and was not J-qualified during data validation), an observed release was established when the sample measurement was three times or more above the highest background. Background concentrations qualified with a J during data validation were not used for sample comparison because background levels were established with data that were not J-qualified.
- If a sample measurement was qualified with a J during data validation, the analysis did not meet all QA/QC requirements and is considered to be an approximate concentration. Because the nature of the sample bias was not provided, it was considered unknown and an adjustment factor was applied to the data before comparing it to the background concentration (ref. 23, pp. 7 and 8). The following adjustment factors were provided by ref. 23: 4,4-DDD, 10.0; 4,4-DDE, 10.0; 4,4-DDT, 12.82. No adjustment factors were provided for DDMU or the 2,4- isomers of DDD, DDE, or DDT; therefore, J qualified data for these substances were not used (ref. 23, p.16). None of the PCB results were J-qualified. If a sample measurement was J-qualified, it was divided by the appropriate adjustment factor and then compared to the background concentration to see if the sample measurement was three times or more above background.

For example, the 4,4-DDE sample result at the 16-20 cm increment in core sample 160-B1 (Station 514) was 10,800 ppb, qualified with SC/J (see Table 5b). This value was divided by 10.0 to get 1,080 as a sample value. The highest background concentration for this compound at this increment was 337 ppb (see Table 4b). Three times 337 is 1,011. Because 1,080 is greater than 1,011, this sample result meets the observed release criteria in ref. 1, Table 2-3.

Attribution

As effluent emissions of hazardous substances decreased in the early 1970s, the effluent-affected sediments were buried with less contaminated effluent and natural sediment (ref. 5, p. 2; ref. 6, p. 3.3). The highest concentrations of DDE are buried by 30 to 50 cm of sediment (ref. 3, pp. 105, 108, 111, 117). Despite the burial by progressively cleaner particles, the concentration of hazardous substances in the surface sediments is greater than would be expected from the contaminant emission rates through the JWPCP discharge (ref. 5, pp. 2-3). Sediment mixing by biological and physical processes and particulate resuspension from waves, currents, and storms contribute to the continuing release of hazardous substances to surface water and into the food chain (ref. 3, pp. ES-7, ES-8, 29; ref. 5, pp. 2-4; ref. 6, p. 3.3).

■ Analyte concentration meets the definition of an observed release (Ref 1, Table 2-3). If data is qualified with a /J, an adjustment value was applied as described in Ref. 23. For 4,4-DDD and 4,4-DDE, the sample result was divided by 10 before applying the criteria in Ref. 1, Table 2-3. For 4,4-DDT, an adjustment factor of 12.82 was applied (ref. 23, pp. 7, 8, 16).

NA = Not available.

Data Qualifiers (ref. 9, p. vi):

U Analyte was not detected. Reported value is the method detection limit.

J Confirmed as present, but at a concentration less than the method detection limit.

NCA Analyte could not be confirmed on the second GC column because of analytical interferences.

SC Surrogate was diluted out of range. Result was corrected for the surrogate recovery in the undiluted analysis of the same sample extract. Data validators determined that the data met accuracy and precision requirements.

/J The reported concentration may not be accurate, as judged by associated calibration, reference material, and/or matrix spike results, or precise, as judged by associated replicate results. Overall goals for results at least five times above the method detection limit were approximately $\pm 50\%$ for precision and $\pm 35\%$ for accuracy.

4.1.2 Drinking Water Threat

Although an observed release of total PCBs and DDT and its metabolites to the ocean on the Palos Verdes Shelf has been documented (see Section 4.1.1.2), the ocean is not used as a drinking water source nor is it used for irrigation, livestock watering, or as an ingredient in commercial food preparation. The area of contaminated sediments on the Palos Verdes Shelf is far enough offshore that it would not constitute a major or designated recreation area. For these reasons, the Drinking Water Threat was not scored.

Drinking Water Threat Score: 0

4.1.3 Human Food Chain Threat

4.1.3.1 Likelihood of Release

An observed release of total PCBs and DDT and its metabolites to the ocean on the Palos Verdes Shelf has been documented (see Section 4.1.1.2). This water body is part of a fishery (ref. 19, p. 2); therefore the Human Food Chain Threat is evaluated (see Section 4.1.3.3).

Likelihood of Release Factor Category Value: 550

4.1.3.2 Waste Characteristics

4.1.3.2.1 Toxicity/Persistence/Bioaccumulation Factor

Table 6 presents the toxicity, persistence, and bioaccumulation factors for 4,4-DDE, 4,4-DDD, 4,4-DDT, and PCBs. The highest toxicity/persistence/bioaccumulation factor for the Human Food Chain Threat is 5×10^8 for PCBs (ref. 2, pp. B-6 and B-16).

Table 6					
Waste Characteristics					
Hazardous Substance	Toxicity	Persistence	Bioaccumulation	Factor Value	Reference
4,4-DDE	100	1	50,000	5×10^6	2, p. B-6
4,4-DDD	100	1	50,000	5×10^6	2, p. B-6
4,4-DDT	1,000	1	50,000	5×10^7	2, p. B-6
PCBs	10,000	1	50,000	5×10^8	2, p. B-16

4.1.3.2.2 Waste Quantity

The Hazardous Waste Quantity assigned from Section 2.4.2 is 3.68×10^6 . The Hazardous Waste Quantity factor value assigned by ref. 1, Table 2-6 is 1,000,000. Because actual contamination of a fishery is documented (see Section 4.1.3.3.1), the default hazardous waste quantity for the Human Food Chain Threat is 100; the Hazardous Waste Quantity factor value for the site is the greater of these two numbers, or 1,000,000 (ref. 1, Section 2.4.2.2).

4.1.3.2.3 Waste Characteristics Factor Category Value

Multiplying the Toxicity/Persistence factor value of 10,000 by the Hazardous Waste Quantity factor value of 1,000,000 equals 1×10^{10} . This value is subject to a maximum of 1×10^8 (ref. 1, Section 2.4.3.2). The value 1×10^8 multiplied by the Bioaccumulation value of 50,000 equals 5×10^{12} , which produces a Waste Characteristics Factor Category value of 1,000 for the Human Food Chain Threat (ref.1, Section 2.4.3.2 and Table 2-7).

Waste Characteristics Factor Category Value: 1,000

4.1.3.3 Human Food Chain Threat Targets

4.1.3.3.1 Food Chain Individual

The ocean waters on top of the effluent-affected sediments are subject to an observed release (see Section 4.1.1.2). Several fisheries of the Southern California Bight incorporate the waters off the Palos Verdes Peninsula, and therefore, the area of the observed release (ref. 22, pp.16, 17, 32; ref. 24, pp. xxii and 23). Fish species known to be caught in the area of the White's Point outfall include sculpin (*Scorpaena guttata*), rockfish species (*Scorpaenidae*), kelp bass (*Paralabrax clathratus*), bonito (*Sarda chiliensis*), mackerel (*Scomber japonicus*), sand dab (*Citharichthys sordidus*), white croaker (*Genyonemus lineatus*), queenfish (*Serphus politus*), surfperch species (*Embiotocidae*), and opaleye (*Girella nigricans*) (ref. 24, pp. xxi, xxii and 23).

Both the commercial and sport white croaker fishery in the vicinity of the White's Point sewage outfalls is closed due to high levels of DDT and PCBs in fish tissue (ref. 17, p.1; ref. 18, pp. 1 and 2; ref. 19, p. 2). The California Environmental Protection Agency's Office of Environmental Health Hazard Assessment (OEHHA) has issued warnings against consuming white croaker off the Palos Verdes Peninsula annually since 1985; the fish has been banned from commercial fishing in this area since 1990 (ref. 17, p. 1; ref. 18, p. 1). Although the white croaker fishery is the only closed fishery, OEHHA has also recommended that consumption of sculpin, rockfishes, and kelp bass caught in the White's Point area be limited to no more than one meal every two weeks for all three species combined (ref. 19, p. 2; ref. 24, p. 149).

Both juvenile and adult white croaker are benthic feeders foraging for polychaetes and crustaceans over open sandy bottoms (ref. 20, p. 3-15). White croaker are tolerant of degraded environments and are often found around sewage outfalls (ref. 20, p. 3-15). Studies conducted on white croaker contamination show that DDE levels in the fish decline sharply away from the outfall and that PCB congeners differ in croaker close to the outfall from croaker farther away (ref. 20, p. 3-16). Both data support the assumption that white croaker have only limited movement along the shelf and that they remain in the same area throughout their lives (ref. 20, p. 3-16).

Because the white croaker fishery is closed, and a hazardous substance for which the fishery is closed (PCBs and DDT) has been documented in an observed release to the watershed from the site, level II contamination is assigned to the fishery. A food chain individual value of 45 is assigned (ref. 1, Section 4.1.3.3.1).

4.1.3.3.2 Population

Although Level II contamination is assigned to the white croaker fishery on the Palos Verdes Shelf, no fishery production data are available. Commercial fish catch data identify the poundage of fish landed at a particular port, not where the fish were caught (ref. 21, p. 1). Recreational fishery statistics cover too broad an area (the entire Southern California Bight) to get numbers specific to the Palos Verdes Shelf (ref. 22, pp. 16, 17, 32). Therefore, food chain population was assigned a minimum value of 0.03 assuming that production is greater than 0 pounds per year (ref. 1, Table 4-18).

4.1.3.3.3 Targets Factor Category Value

Summing the Human Food Chain Individual factor value and the Population factor value produces a Targets Factor Category value of 45.03.

Human Food Chain Targets Factor Category Value: 45.03

Human Food Chain Threat Score: 100.00

4.1.4 Environmental Threat

4.1.4.1 Likelihood of Release

An observed release has been documented to the waters of the Palos Verdes Shelf (see Section 4.1.1.3). The Palos Verdes Shelf is part of the habitat for several federally endangered or threatened species including humpback whale (*Megaptera novaeangliae*), brown pelican (*Pelecanus occidentalis*), bald eagle (*Haliaeetus leucocephalus*), peregrine falcon (*Falco peregrinus*) (see Section 4.1.4.3).

Likelihood of Release Factor Category Value: 550

4.1.4.2 Waste Characteristics

4.1.4.2.1 Ecotoxicity/Persistence/Bioaccumulation Factor

Table 7 presents the ecotoxicity, persistence, and environmental bioaccumulation factors for 4,4-DDE, 4,4-DDD, 4,4-DDT, and PCBs. All four compounds produce the highest ecotoxicity/persistence/bioaccumulation factor for the Environmental Threat at 5×10^8 .

Table 7					
Waste Characteristics					
Hazardous Substance	Ecotoxicity	Persistence	Bioaccumulation	Factor Value	Reference
4,4-DDE	10,000	1	50,000	5×10^8	2, p. B-6
4,4-DDD	10,000	1	50,000	5×10^8	2, p. B-6
4,4-DDT	10,000	1	50,000	5×10^8	2, p. B-6
PCBs	10,000	1	50,000	5×10^8	2, p. B-16

4.1.4.2.2 Waste Quantity

The Hazardous Waste Quantity assigned from Section 2.4.2 is 3.68×10^6 . The Hazardous Waste Quantity factor value assigned by ref. 1, Table 2-6 is 1,000,000. Because actual contamination of sensitive environments is documented (see Section 4.1.4.3), the default hazardous waste quantity for the Environmental Chain Threat is 100; the Hazardous Waste Quantity factor value for the site is the greater of these two numbers, or 1,000,000 (ref. 1, Section 2.4.2.2).

4.1.4.2.3 Waste Characteristics Factor Category

Multiplying the Ecotoxicity/Persistence factor value of 10,000 by the Hazardous Waste Quantity Factor Value of 1,000,000 equals 1×10^{10} . This value is subject to a maximum of 1×10^8 (ref. 1, Section 2.4.3.2). The value 1×10^8 multiplied by the Bioaccumulation value of 50,000 equals 5×10^{12} , which produces a Waste Characteristics Factor Category value of 1,000 for the Human Food Chain Threat (ref. 1, Section 2.4.3.2 and Table 2-7).

Waste Characteristics Factor Category Value: 1,000

4.1.4.3 Environmental Threat Targets

The ocean water above the effluent-affected sediments is part of the habitat for five federally listed endangered or threatened species: humpback whale, brown pelican, bald eagle, and peregrine falcon:

Humpback whale

According to the National Marine Fisheries Service's *Final Recovery Plan for the Humpback Whale* (1991), humpback whales have been seen migrating in the coastal waters of the San Pedro Channel (between Santa Catalina Island and the Palos Verdes Peninsula) (ref. 4; ref. 25, p. 17). It is not clear if the whales use these waters for purposes other than migration, but they have been seen feeding along the migration corridor (ref. 25, pp. 17-18). The humpback whale was listed as a federally endangered species in 1970 (ref. 28, p. 9, 30).

Brown pelican

The brown pelican feeds almost entirely on fish. It catches fish by diving from 6 to 12 meters in the air to either deep or shallow waters (ref. 26, p. 20). It breeds on the Channel Islands and disperses along the entire California coast after breeding (ref. 26, p. 20 and 21). The area off the Palos Verdes Peninsula is considered part of the pelican's summer and winter range (ref. 26, p. 21). The virtually complete reproductive failure of the brown pelican population in the Channel Islands (Anacapa Island) in 1968-1969 led to its listing as federally endangered in 1970 and played a significant role in the banning of DDT from use in the U.S. in 1972 (ref. 14, p. 11; ref. 27, p. 38; ref. 28, pp. 14, 30).

Bald Eagles

The widespread use of DDT, in combination with illegal shooting and habitat loss, led to the bald eagle's decline and designation as an endangered species in 1967 (ref. 29, p. 146; ref. 28, pp. 11, 30). Eggshell thinning is a sensitive indicator of the adverse effect of DDT and its metabolites on avian species (ref. 14, p. 3). DDE is the only chemical known to cause eggshell thinning at environmental levels (ref. 14, p. 3). The levels of DDE in bald eagles on Santa Catalina Island are much too high to allow successful reproduction (ref. 14, p. 12). The average value of DDE residue levels in eggs from Santa Catalina Island is 33.7 ppm which is 10 times higher than the level at which adverse reproductive effects can be expected (ref. 14, p. 5, 12). Reproduction has only been possible using artificial incubation and even then the success rate is very low (ref. 14, p. 5). Biomagnification via gulls and marine mammals is considered to be the major factor in the contamination of bald eagles on Santa Catalina Island (ref. 14, p. 6).

Santa Catalina Island bald eagles are a relatively sedentary population moving only small distances for food (ref. 14, p. 6). They are generalists and opportunistic feeders taking a variety of prey species either live or as carrion (ref. 14, p. 6). Although fish form the bulk of their diet, birds contribute 9 to 19 percent of their diet and marine mammal carrion contributes about 2 percent (ref. 14, p. 6). Bald eagles have been known to feed 16 to 19 km from their nesting areas (ref. 26, p. 122).

Peregrine Falcons

The peregrine falcon disappeared from the Channel Islands in the early 1950s and there are no records of any sightings from 1950 to 1972 (ref. 14, p. 7). They were listed as a federally endangered species in 1970 (ref. 28, pp. 12, 30). Due to a large reintroduction program in the late 1970s and 1980s, some

successful breeding of peregrine falcon now occurs in the Channel Islands (ref. 14, p. 7). Following the ban of the use of DDT, substantial recovery in eggshell thickness has occurred throughout the world; however, the eggshell thickness of peregrines on the central California coast and the Channel Islands has shown no significant improvement in recent years (ref. 14, p. 7). The degree of eggshell thinning now observed in the Channel Islands is likely the highest in the world (ref. 14, p. 8).

Adult peregrine falcons are resident to the Channel Islands, but they feed on a wide variety of avian species (ref. 14, p. 7). They feed almost exclusively on birds; over 50 species of birds have been observed as prey on the Channel Islands (ref. 20, p. 5-23). Although Channel Island peregrines eat some migratory prey, the proportion of migratory prey is lower than that taken by other peregrine populations (ref. 14, p. 7). The home range of the peregrine falcon extends up to 23 km from its nest; size of range fluctuates with prey availability (ref. 26, p. 148).

Although the spacial pattern of DDE contamination in surface sediment samples from Mexico to Northern California show a distinct peak at the Palos Verdes Shelf, there have been few attempts to demonstrate the link between a source of hazardous substances and contamination in sensitive species (ref. 20, p. E-1). Other potential sources of contamination to the coastal biota include migrant birds, migrant fish, runoff from agricultural fields in which Kelthane was used, residual DDT in agricultural fields, global fallout, illegal DDT use, and other coastal sources of PCBs (ref. 20, p. E-4).

A study was conducted as part of the NRDA for the Southern California Bight to determine what concentration of DDE and PCBs needed to be in prey to account for the concentrations found in bald eagles, peregrine falcons and double-crested cormorants inhabiting the Channel Islands, and whether the estimated dietary concentrations indicate that the species must have received much of their contaminant load from prey species in the Palos Verdes area (ref. 20, p. E-7). Model results indicate that levels of DDE and PCBs found in marine birds of the Channel Islands are sufficient to account for the levels observed in peregrine falcons eggs from the Channel Islands (ref. 20, pp. 5-44, 6-3). The modeling also showed that Santa Catalina Island bald eagles receive at least half, and possibly all of their contaminant loads from birds, fish, and mammals caught in the vicinity of the island. Levels of DDE and PCBs in the fish of the Southern California Bight were sufficient to account for contaminant levels in cormorants nesting on Anacapa Island; however, cormorants from Santa Barbara Island (farther north) exhibited lower levels of contaminants suggesting that they may be feeding at least in part from areas that are less contaminated (ref. 20, p. 6-3).

Although it cannot be shown that all of the DDE and PCBs observed in brown pelicans, bald eagles and peregrine falcons comes from local sources (i.e., the Palos Verdes Shelf), it is likely that this is an important source. These species are relatively non-migratory as is much of their prey (ref. 14, p. 12). There is no good evidence that levels of DDT in Latin America are high; DDT has been banned or severely restricted in all Latin American countries along the Pacific Ocean (ref. 14, p. 12). In addition, migratory populations of peregrine falcon have shown marked improvements whereas the reproductive problems and degree of eggshell thinning of the peregrines in the Channel Islands remains high (ref. 14, p. 12). Finally, the DDT to DDE ratio of the contamination found in the avian species is low, indicating that the source of the DDT is old (ref. 14, p. 12).

4.2.4.3.1.2 Level II Concentrations

The area of the Palos Verdes Shelf documented by an observed release of hazardous substances to the ocean is part of the habitat of brown pelican, bald eagles and peregrine falcon living in the Channel Islands because they feed on prey that have accumulated 4,4-DDE and PCBs through the food chain (ref. 14, pp. 11-12; ref. 20, p. 6-3). Humpback whales are known to forage in the channel above the Palos Verdes Shelf (ref. 25, pp. 17-18).

Table 8				
Sensitive Environment Targets				
Target	Sensitive Environment Classification	Rating Value	Level of Contamination	Assigned Factor Value
Brown pelican (<i>Pelecanus occidentalis californicus</i>)	Habitat known to be used by Federal designated or proposed endangered or threatened species	75	II	75
Bald eagle (<i>Haliaeetus leucocephalus</i>)	Habitat known to be used by Federal designated or proposed endangered or threatened species	75	II	75
Peregrine falcon (<i>Falco peregrinus</i>)	Habitat known to be used by Federal designated or proposed endangered or threatened species	75	II	75
Humpback whale (<i>Megaptera novaeangliae</i>)	Habitat known to be used by Federal designated or proposed endangered or threatened species	75	II	75
Total				300

4.1.4.3.1.3 Potential Contamination

Many sensitive environments exist within the 15-mile target distance limit from Source 1 including, but not limited to: habitat known to be used by the California least tern (*Sterna antillarum browni*), a federally listed endangered species (ref. 26, pp. 278-279); Abalone Cove Ecological Reserve and Point Fermin Wildlife Refuge (ref. 27, p. 201); and Santa Monica Bay National Estuary (ref. 30). Because the dilution weighting factor for coastal tidal waters and shallow ocean zone, where most of the sensitive environments within the 15-mile target distance limit occur, is 0.0001, documenting the presence of these sensitive environments would not contribute significantly to the overall Environmental Threat score (ref. 1, Table 4-13).

Sensitive Environments Target Factor Category Value: 300

Environmental Threat Score: 100.00

5.0 SOIL EXPOSURE PATHWAY

The soil exposure pathway was not quantified because the effluent-affected sediments sit under 30 to 500 m of ocean water (ref. 3, p. 120).

6.0 AIR PATHWAY

The air pathway was not quantified because the effluent-affected sediments sit under 30 to 500 m of ocean water (ref. 3, p. 120).
